Abstract

Objective: This study investigates the spatiotemporal variations in land use/land cover (LULC), surface temperature, and surface energy flux components in Ahmedabad, India, from 2014 to 2024. **Method:** using Landsat 8 (OLI/TIR) imagery and the SEBAL (Surface Energy Balance Algorithm for Land) model on the Google Earth Engine (GEE) platform. **Findings:** Results reveal a significant increase in built-up areas from 27% to 36% and a decline in natural vegetation from 23% to 17%, indicating rapid urban expansion and environmental stress. Land Surface Temperature (LST) increased by 3.16°C over the decade, exhibiting a strong inverse correlation with the Normalized Difference Vegetation Index (NDVI), thereby highlighting the impact of vegetation loss on urban heat amplification. Surface energy flux analysis showed a 7.7% increase in net radiation (Rn) and consistently elevated sensible heat flux (H), particularly in urban cores, while latent heat flux (LE) and evapotranspiration (ET) remained relatively low and confined to vegetated areas. Seasonal comparisons further emphasize higher Rn and H values during summer, with LE peaking in the monsoon due to increased moisture and vegetation activity. Correlation analysis confirmed a strong positive relationship between ET and LE ($R^2 = 0.780$) and a negative correlation with H ($R^2 = 0.768$), underscoring the importance of vegetation in moderating urban microclimates. **Novelty:** These findings indicate that rapid urbanization intensifies thermal stress and alters surface energy dynamics in the study area, emphasizing the necessity of integrating vegetation-focused climate adaptation measures into urban planning. Future research should validate these findings *in situ* and extend the approach to other semi-arid cities for broader climate adaptation planning.

Keywords: Surface Energy Balance; Remote Sensing; Thermal Dynamics; Urbanization Impacts; Land Use Change

1 Introduction

The development in terms of urban sprawl at the expense of natural land cover has also become a major cause of climate variability both locally and regionally. Urbanization has a significant impact on affecting the Surface Energy Balance (SEB) due to changes in land cover, surface roughness, albedo, emissivity, and moisture availability. The alterations of such changes disturb the natural process of splitting the incoming solar radiation into the net radiation (R_n), sensible heat flux (H), latent heat flux (LE) and ground heat flux (G) thus worsening the power of beholding urban heat island (UHI) intensity and abridging the resiliency of the urban climate⁽¹⁾. Nonetheless, along with the increasing attention to the role of the surface energy exchanges in urban microclimate formulation, the existing gap in high-resolution, seasonally specific, and geographically situated research is notable, especially in semi-arid Indian cities where vegetation and urban morphology changes enormously depending on the season⁽²⁾.

Surface Energy Balance Algorithm for Land (SEBAL) and Surface Energy Balance System (SEBS), which have become one of the standard methods to estimate the SEB components with the help of satellite-based data like land surface temperature (LST), normalized difference vegetation index (NDVI), albedo, and emissivity⁽³⁾,⁽⁴⁾. However, several studies in which these models have been used were based on coarse spatial resolution data like MODIS or AVHRR (250–1000 m) of adequate data in terms of regional extent climate. When it comes to evaluating climate at the city scale, such approaches are often insufficient for capturing the intra-urban variability necessary for detailed spatial analysis⁽⁴⁾. Simplification of localized variation in surface energy fluxes yields a simplistic view of the urban thermal processes, in particular, in heterogeneous cities where the contrast between land cover and imperviousness tends to be strong and significant⁽⁵⁾. Medium resolutions, such as Landsat 8, capable of at least 30 m spatial optical and 100 m spatial thermal and nearly a 100 percent increase in spatial extremes and variation in urban form resolution, pose tremendous benefits to the urban SEB research⁽⁵⁾. In addition, the development of cloud computing tools, including Google Earth Engine (GEE), to combine Landsat data and their availability has allowed researchers to analyze numerous and long-running data sets of geospatial information within a reasonable time⁽⁶⁾. Nevertheless, limited studies have been done to utilize the full potential of Landsat 8 to estimate the total components of SEB (in a multi-year and multi-season urban setting) in an Indian environment. Most existing studies have primarily addressed specific SEB components such as land surface temperature (LST) and evapotranspiration (ET), focusing on short-term periods that inadequately capture interannual variability and long-term urbanization effects⁽⁷⁾.

Recent studies have examined surface energy balance (SEB) components in urban areas across India and Los Angeles. In Indian cities, sensible heat flux (SHF) increased while latent heat flux (LHF) slightly decreased from 2000–2018, with SHF showing a positive correlation to land surface temperature⁽³⁾. Urban areas and bare soil exhibited higher ground heat flux ratios compared to vegetated areas, while vegetation and water bodies showed higher LHF ratios⁽⁸⁾. In a semi-arid region of the Deccan Plateau, SHF dominated over LHF even during the monsoon season, with soil moisture and net radiation playing crucial roles in surface flux partitioning. In Los Angeles, latent heat fluxes displayed spatial and temporal responses to irrigation and regional climate, with peak latent heat occurring 3 hours before solar noon due to early morning irrigation practices⁽⁹⁾. Comparative studies between cities with distinct climates but similar summer conditions reveal that vegetation fraction is inversely related to Bowen ratios, while impervious surfaces correlate positively with sensible heat partitioning⁽¹⁰⁾. These findings highlight the importance of considering both spatial and climatic contexts when designing urban areas to mitigate urbanization effects on local climate.

The study addresses research gaps by conducting a decade-long (2014–2024) spatiotemporal analysis of the urban surface energy balance in Ahmedabad, using Landsat 8 satellite images and the SEBAL model within the Google Earth Engine (GEE) platform. It utilized variables obtained from satellite data, such as land surface temperature (LST), NDVI, albedo, and emissivity, to estimate main surface energy balance (SEB) parameters such as net radiation (R_n), sensible heat flux (H), latent heat flux (LE), and ground heat flux (G) with seasonal resolution of summer and monsoon seasons. The research examines the variability in spatial-temporal fluxes and evaluates the effect of seasonal land-use change, which contributes to a better understanding of urban energy dynamics in data-scarce environments. A study investigates the effects of urban development and vegetation coverage on the spatial pattern as well as the temporal aspects of surface energy fluxes. The results help understand urban thermal dynamics and contribute to the creation of climate-resilient strategies of urban planning.

2 Methodology

Ahmedabad, the largest metropolitan city in western India, is situated in the state of Gujarat and geographically spans between coordinates 23°09′54.68″N, 72°33′40.02″E and 22°54′19.90″N, 72°39′51.62″E, along the Sabarmati River⁽¹¹⁾. The river separates the city into eastern and western sectors. Covering an area of approximately 720 km², the metropolis has an estimated population of seven million.

Fig 1. Study area

The eastern region is marked by high-density development, narrow road networks, and a concentration of manufacturing industries, all of which significantly influence elevated Land Surface Temperature (LST) levels. Conversely, the western region exhibits relatively modern infrastructure, intermittent green spaces, and recreational zones. Ahmedabad experiences an arid climate, with summer temperatures often exceeding 45°C during April and May. In contrast, winter temperatures range between 30°C and 35°C, while the monsoon period, from July to September, brings more moderate and comfortable weather conditions. Urban land use and planning are managed by the Ahmedabad Municipal Corporation (AMC) and the Ahmedabad Urban Development Authority (AUDA).

Landsat 8 satellite imagery was employed to estimate Land Surface Temperature (LST), generate vegetation indices, and analyze surface energy flux parameters. Data spanning the period from 2014 to 2023 were processed using the Google Earth Engine (GEE) platform. The analysis utilized the Landsat 8 Collection-2 Tier-1 dataset (LANDSAT/LC08/C02/T1_L2), which provides Brightness Temperature (BT) and Top-of-Atmosphere (TOA) reflectance values. Landsat 8 carries two primary sensors: the Operational Land Imager (OLI) and the Thermal Infrared Sensor (TIRS) (USGS, 2024)⁽¹²⁾. The OLI captures multispectral, non-thermal imagery at a spatial resolution of 30 meters (Table 1), primarily used for mapping land surface features. In contrast, TIRS collects thermal infrared data at a spatial resolution of 100 meters, which is essential for deriving LST⁽¹⁾.

Table 1. Dataset used in this Study

Dataset	Landsat-8 (OLI / TIR)
Data Collection from GEE	LANDSAT/LC08/C02/T1_L2
Resolution	OLI: 30 m (Band 2, 4, 5, 6, 7) TIR: 100 m (Band 10)
Band Information	B2: Blue (0.45 – 0.51 μ m) B4: Red (0.64 – 0.67 μ m) B5: NIR (0.85 – 0.88 μ m) B5: SWIR1 (1.57 – 1.65 μ m) B5: SWIR2 (2.11 – 2.29 μ m) B10: TIR (10.6 – 11.19 μ m)

Figure 2 illustrates the comprehensive methodology flowchart developed for the estimation of Land Surface Temperature (LST), vegetation indices, albedo, surface energy flux components, and evapotranspiration over the urban and peri-urban regions of Ahmedabad for the period 2014–2023. The entire analysis was carried out using Google Earth Engine (GEE), a cloud-based geospatial analysis platform. Initially, Landsat 8 imagery was loaded and preprocessed, including cloud masking using the QA_PIXEL band to remove pixels flagged as clouds or cloud shadows through standard bitwise operations. Radiometric and atmospheric corrections were applied using official Landsat scaling factors to ensure accurate surface reflectance values.

Fig 2. Flow chart of Methodology

The Brightness Temperature (B_T) is calculated using the thermal band of Landsat-8 as shown in **equation (1)**⁽³⁾.

$$B_T = \left(\frac{K_2}{\ln \left(\frac{K_1}{L} + 1 \right)} \right) - 273.15 \quad (1)$$

Here, K_1 and K_2 are band-specific calibration constants in Kelvin, and B_T represents the effective satellite temperature, the K_1 and K_2 constants from the OLI/TIRS sensor.

The Normalized Difference Vegetation Index (NDVI) is derived using the Red (Band 4) and Near-Infrared (NIR, Band 5) bands with **equation (2)**⁽⁶⁾.

$$NDVI = \frac{NIR - Red}{NIR + Red} \quad (2)$$

Land Surface Emissivity (LSE) is estimated using NDVI thresholds as per **equation (3)**.

$$Emissivity (E_m) = 0.004 \cdot P_v + 0.986 \quad (3)$$

The fraction of vegetation (P_v) is computed from NDVI values using **equation (3a)**.

$$P_v = \left(\frac{NDVI - NDVI_{min}}{NDVI_{max} - NDVI_{min}} \right)^2 \quad (3a)$$

The Land Surface Temperature (LST) is calculated using B_T and E_m values in **equation (4)**⁽⁵⁾.

$$LST = \frac{B_T}{1 + \left(0.00115 \cdot \frac{B_T}{1.438} \cdot \ln(E_m)\right)} \quad (4)$$

Using **equations (2) and (4)**, Annually mean values of NDVI and LST were calculated for the period from 2014 to 2023.

In addition the surface Albedo (α) is estimated using the reflectance values from the visible, near-infrared, and shortwave infrared bands of Landsat-8. It quantifies the ability of surface to reflect solar radiation⁽¹³⁾.

$$\alpha = 0.356 \cdot B_{Blue} + 0.130 \cdot B_{Red} + 0.373 \cdot B_{NIR} + 0.085 \cdot B_{SWIR1} + 0.072 \cdot B_{SWIR2} - 0.0018 \quad (5)$$

B_{Blue} , B_{Red} , B_{NIR} , B_{SWIR1} , and B_{SWIR2} are the surface reflectance values of Landsat 8 Bands 2, 4, 5, 6, and 7, respectively.

The incoming shortwave radiation ($R_s \downarrow$) was estimated using surface albedo and solar geometry parameters (solar zenith angle, earth-sun distance) extracted from the Landsat metadata⁽⁷⁾. The outgoing longwave radiation ($R_l \uparrow$) was approximated using the Stefan–Boltzmann Law, assuming surface temperature as a proxy for atmospheric temperature:

$$R_l \uparrow = \epsilon \cdot \sigma \cdot T_s^4 \quad (6)$$

Where, ϵ is the surface emissivity; $\sigma = 5.67 \times 10^{-8} \text{ W} \cdot \text{m}^{-2} \cdot \text{K}^{-4}$ is the Stefan–Boltzmann constant; T_s is the land surface temperature in Kelvin

Using the above inputs from **equation (6) and (5)**, Net Radiation (R_n), which represents the total available energy at the surface, was calculated using the following energy balance equation:

$$R_n = (1 - \alpha) \cdot R_s \downarrow + \epsilon \cdot R_l \downarrow - \epsilon \cdot \sigma \cdot T_s^4 \quad (7)$$

Where, α is the surface albedo; $R_s \downarrow$ is the incoming shortwave radiation; $R_l \downarrow$ is the incoming longwave radiation; $\epsilon \cdot \sigma \cdot T_s^4$ represents the outgoing longwave radiation ($R_l \uparrow$).

The soil heat flux (G), which represents the conductive energy flux into the ground⁽¹⁴⁾. This formulation integrates R_n , albedo and vegetation dynamics from **equation (7), (5), (2)** to modulate soil heat flux based on surface cover characteristics.

$$G = R_n \cdot ((T_s - 273.15)(0.0038 + 0.0074 \cdot \alpha)(1 - 0.98 \cdot (NDVI)^4)) \quad (8)$$

Where, R_n is the net radiation (W m^{-2}); T_s is the land surface temperature in Kelvin; α is the surface albedo; NDVI is the Normalized Difference Vegetation Index.

The sensible heat flux (H) is calculated based on the temperature gradient between the land surface and the near-surface air⁽³⁾, using the following equation (**Eq. 9**):

$$H = \frac{\rho \cdot Cp \cdot (T_s - T_a)}{r_{ah}} \quad (9)$$

Where, ρ is the air density ($\text{kg} \cdot \text{m}^{-3}$); Cp is the specific heat of air at constant pressure ($1005 \text{ J} \cdot \text{kg}^{-1} \cdot \text{K}^{-1}$); T_s is the land surface temperature (K); T_a is the near-surface air temperature (K); r_{ah} is the aerodynamic resistance to heat transport ($\text{s} \cdot \text{m}^{-1}$).

The near-surface air temperature (T_a)⁽¹⁵⁾ was obtained from the ERA5-Land reanalysis dataset, provided by the European Centre for Medium-Range Weather Forecasts (ECMWF) and accessible via Google Earth Engine (GEE). This dataset offers hourly land-atmosphere variables at a spatial resolution of approximately 2 m. For the city of Ahmedabad, characterized by an urban landscape interspersed with vegetated areas, an aerodynamic resistance (r_{ah}) value of $60 \text{ s} \cdot \text{m}^{-1}$ was assumed.

The latent heat flux (LE), which indicates the amount of energy used for evapotranspiration, is obtained as the residual of the energy balance equation⁽²⁾:

$$LE = R_n - G - H \quad (10)$$

Finally, the actual evapotranspiration (ET) in mm/day is derived using the latent heat flux (LE), and the latent heat of vaporization ($\lambda = 2.45 \times 10^6 \text{ J/kg}$), as shown below⁽⁴⁾:

$$ET = \frac{LE \cdot 86400}{\lambda} \quad (11)$$

Where, 86400 is the number of seconds in a day. This approach enables pixel-wise ET estimation from satellite data across spatial and temporal domains.

In the final phase of the methodology, the impact of urbanization on vegetation cover and surface energy dynamics in Ahmedabad was assessed by analyzing long-term trends in NDVI, LST, and surface flux components. Using seasonal and annual raster datasets derived from Google Earth Engine, correlation analysis was performed to explore the interrelationship among variables⁽²⁾. Specifically, the Pearson correlation coefficient was used to evaluate the linear associations between NDVI, LST, and net radiation (Rn), as well as between albedo and Rn, and LST and Rn. These relationships provide insights into how urban expansion influences surface energy balance and vegetation dynamics⁽³⁾. Seasonal variation in surface fluxes was also analyzed, particularly comparing summer and monsoon periods, to understand the thermal and moisture redistribution under changing land use⁽¹³⁾. Furthermore, correlations between LE and H, and between LE and ET, were computed to assess how energy partitioning affects evapotranspiration processes in the urban landscape. These analyses helped in identifying spatial and temporal patterns of land-atmosphere interactions under the pressure of urban growth and climatic variability.

3 Results and Discussion

Analysis of surface energy flux components derived in Landsat 8 (OLI/TIR) imagery by the SEBAL model in the cloud-based Google Earth Engine (GEE) platform describes considerable annual tendencies in energy partitioning in the city of Ahmedabad between 2014-2024 as the effects of the vegetation dynamics and continuous urbanization in the city.

3.1 Land Use Change Detection

The evaluation of land use and land cover (LULC) dynamics across the decade of 2014-2024 in Ahmedabad indicates a sharp anthropogenic change in tune with that of urbanization witnessed in other semi-arid cities of India. As Figure 3 shows, there is a strong upward trend, with 27% of the built-up area in 2014 and 36% in 2024, which is a net increase of 9%. This pattern is consistent across the largest cities of India, where urban growth predominantly occurs through edge expansion, leading to the fragmentation of tree cover, agricultural lands, and water bodies⁽¹⁶⁾. At the same time, the natural plants dropped sharply from 23% to 17%, showing that there was a lot of stress on the environment because of changes in land use, a finding also noted in the study by Vaishnav et al. (2024)⁽¹⁷⁾, which linked the loss of plants to higher water loss in growing urban areas. The growth in usable land, which is barren and goes up by 32% to 39%, indicates the advent of transitional surfaces before impervious development. These trends in combination highlight the emergence of the city as an increasingly impervious landscape, which increases the problem of surface energy imbalance and the development of urban heat islands (UHI). Despite the change in water bodies marginally to 2%, as compared to 1%, in the given period, the small addition can be either due to an improvement in spatial resolution in Landsat 8 and localized activities like an urban water retention system. These interpretations were also proposed in the urban hydro studies of other municipalities in India⁽¹⁸⁾. Therefore, the LULC modifications in Ahmedabad during the ten years reflect the generalized restructuring of the landscape brought on by urbanization in similar semi-arid regions. Which has serious implications for both the surface energy balance and environmental sustainability of the city and in composition constitutes one of the foundations for the perception of the land surface temperature and heat flux variations.

Fig 3. Land use classification for year (a) 2014 and (b) 2024

3.2 Temporal Analysis of LST and NDVI (2014–2024)

The increasing trend analysis of Land Surface Temperature (LST) and Normalized Difference Vegetation Index (NDVI) of Ahmedabad between 2014 and 2024 shows that there is a substantial negative correlation between LST and NDVI, which highlights the effect of rising temperature due to CO₂ emission in the context of diminishing vegetation cover, which is attributed to the urban sprawl. LST improved between 2014 (38.14°C) and 2024 (41.3°C) in a net increase of 3.16°C over ten years, as shown in Figure 4. The highest temperatures were recorded in 2015 (40.47°C), 2017 (40.68°C), and 2023 (40.96°C).

Fig 4. Temporal Analysis of LST and NDVI (2014–2024)

The NDVI values throughout the period between 2014 and 2024 showed a gradual decline, with 0.411 in 2014 and 0.392 in 2024 recorded which corresponds to a negative 4.6% change despite the existence of interannual variations. Specifically, NDVI decreased by 0.393 in 2018, the year in which local surface temperature (LST) recorded its high value of 40.36°C, and 0.397 in 2023, when LST jumped to its highest on record. These findings have consistently demonstrated an inverse relationship between vegetation and urban temperatures. Chakraborty et al. (2022)⁽¹⁹⁾ found that larger, more connected vegetation patches are more effective at mitigating land surface temperature (LST). Ahmedabad shows a slightly higher increment in LST as compared to other cities, an indication of greater land change. This strong inverse relation between LST and NDVI indicates the importance of urban greening measures in mitigating thermal stress and increasing climate resilience, particularly in rapidly growing urban areas.

3.3 Trends analysis in Surface Energy Fluxes (2014–2024)

Figure 5 contains a spatiotemporal analysis of surface energy balance components-Albedo, Net Radiation (R_n), Soil Heat Flux (G), Sensible Heat Flux (H), Latent Heat Flux (LE), and Evapotranspiration (ET) in the years 2014 and 2024. Albedo maps are highly constant with little difference in surface reflectance in the various maps since the decade; however, a substantial difference in the albedo maps of urban areas as the increase in impervious covers leads to reduced albedo readings. The Net radiation has slightly increased in 2024, especially in the urban cores, because of continued urbanization, which is in line with the rising values of the Soil Heat Flux (G) and Sensible Heat Flux (H) rates, indicating that there was greater heating of the surface and urban heat island effects. Conversely, LE and ET maps indicate comparatively constant and marginally greater values, especially across vegetated and peri-urban regions, which could be due to trees-planting activities, and better management of the land. These results are similar to those of earlier research by Smith et al., (2021)⁽²⁰⁾ that observed urbanized areas with high impervious surface area percentages experience increased sensible heat flux and land surface temperature, while areas with higher vegetation coverage exhibit higher latent heat flux and lower temperatures. This study show that anthropogenic heat discharge contributes to urban warming, with greater impacts in high-density urban areas. Understanding these dynamics is crucial for developing effective urban climate change adaptation strategies

Fig 5. Spatio-temporal Analysis of Surface Fluxes Parameters from Landsat 8 using GEE for Ahmedabad (a) Year - 2014 and (b) Year – 2024

Fig 6. Temporal Analysis of Surface Fluxes (2014–2024)

Decadal analysis of surface energy fluxes in Ahmedabad between 2014 and 2024 shows (Figure 6) that there is a major change in urban surface energy balance, which is also closely related to land cover change and an increase in LST. Net radiation (Rn) showed a consistent growth from 416.66 W/m^2 in 2014 to a high point of 448.9 W/m^2 by the year 2024, an increase of 7.7%. The growth was significantly higher in 2017 (440.19 W/m^2) and 2023 (441.99 W/m^2). The sensible heat flux (H) was the determining factor in the proportions of the energy distribution during the timeframe, with averagely steady high values of $300\text{--}340 \text{ W/m}^2$, and it peaked in the year 2023, a time when there was less plant coverage (NDVI: 0.397) and LST was higher (40.96°C). In comparison, latent heat flux (LE) was restrained with an average amount of $40\text{--}60 \text{ W/m}^2$ and an obvious decrease in the years of strong surface warming. Ground heat flux (G) was less variable and tended to be in the range of $80\text{--}100 \text{ W/m}^2$. These findings suggest that the role of sensible heat is increasing gradually, which is associated with the decline in the vegetation cover and

evapotranspiration, which is also observed by Wang et al., (2021)⁽²¹⁾. Urban and impervious surfaces show higher sensible heat flux ratios, while vegetation and water bodies display higher latent heat flux ratios described by Bala et al., (2022)⁽⁸⁾. These findings underscore the importance of strategic urban vegetation planning for effective heat mitigation and climate adaptation in cities.

3.4 Seasonal Variation in Surface Energy Fluxes (2014–2024)

Analysis of a decade of surface energy flux over Ahmedabad (2014–2024) provides significant differences in the summer and the monsoon seasons shows in Figure 7. The values of net radiation (R_n) are also always higher during summertime, and its approximate values between 580–650 W/m^2 . The higher levels relate to the increased condition of solar isolation and a low extent of cloud cover. Monsoon R_n values vary between 550–630 W/m^2 , these are mostly due to the differences in the solar radiation, the amount of moisture in the atmosphere, and the land-surface properties. The sensible heat flux (H) is also prevailing in summer and is 370–430 W/m^2 and a sharp peak can be observed in 2023. However, monsoon H is more variable, reaching its lowest levels of 290–310 W/m^2 in wet years like 2017 and 2020.

Fig 7. Seasonal variation of Surface Fluxes (2014–2024)

Ground heat flux (G) was slightly larger in summer, with over 160 W/m^2 during 2023 compared to less than 140 W/m^2 during the monsoon. The strongest seasonal variation was observed in the latent heat flux (LE), with monsoon LE peaking at more than 200 W/m^2 throughout 2017 and 2022, whereas LE during summer decreased to less than 70 W/m^2 . These consistently find that urbanized areas have higher sensible heat flux (H) and land surface temperature (LST), while vegetated areas exhibit higher latent heat flux (LE) and lower temperatures⁽²²⁾. The innovation of the study is a decade-scale, seasonally resolved evaluation of urban surface energy fluxes based on high-resolution remote sensing data, which allows detection of both the negligibly small interannual variations and even larger long-term signals in urban climates. The correlation analysis with R^2 values of surface fluxes are further elaborated in Section (4).

3.5 Correlation Analysis

In Figure 8, it is exhibited that Net Radiation (R_n) is connected with the surface parameters between 2014 and 2024, such as Land Surface Temperature (LST), Normalized Difference Vegetation Index ($NDVI$), Albedo, and Evapotranspiration (ET).

R_n is the most positively correlated variable with LST ($R^2 = 0.763$), which is attributed to surface warming caused by urbanization that strongly increases net radiation. The correlation between R_n and $NDVI$ is negative ($R^2 = 0.209$), indicating the cooling effect of vegetation. These results are specific in that they highlight the moderating effect of vegetation that holds

Fig 8. Correlation between (a) R_n – LST, (b) R_n – NDVI, (c) R_n – Albedo, (d) R_n – ET

stability through summer and monsoons, even though the urbanization process continues. The net radiation had the greatest and most direct relationship with LST, which is an indication that the level of heating in the urban environment is associated with elevated radiative forcing⁽²³⁾. There is a weak negative correlation of albedo with R_n ($R^2 = 0.040$) which, observed that albedo has limited influence over dense urban Structures. Correlation between R_n and ET is also weak ($R^2 = 0.097$), but the negative slope implies the importance of evapotranspiration in decreasing R_n .

Fig 9. Correlation between (a) ET – LST, (b) ET – NDVI, (c) ET – LE, (d) H – LE

Figure 9 shows the correlation of Evapotranspiration (ET) and the critical surface variables of Land Surface Temperature (LST), Normalized Difference Vegetation Index (NDVI), Latent Heat Flux (LE), and Sensible Heat Flux (H) over the 2014 - 2024 periods in Ahmedabad, India. The ET and LST relationship depicts poor negative correlation ($R^2 = 0.057$), indicating that an increase in surface temperatures has a low level effect in reducing ET rates. The correlation between ET and NDVI is weak ($R^2 = 0.052$), but theoretically, greater vegetation cover should encourage higher ET. In comparison, ET is highly positively correlated with Latent Heat Flux (LE) ($R^2 = 0.780$) and highly negatively correlated with Sensible Heat Flux (H) ($R^2 = 0.768$). These findings are consistent with previous models⁽⁷⁾, which identify ET as the main driver of energy partitioning, where latent heat flux dominates sensible heat flux in vegetated areas. The originality of the research is associated with the decade-long, multi-variable analysis of ET drivers in a fast urbanizing, semi-arid region conducted with high-resolution satellite information. This study highlights the necessity of preserving green infrastructure and adopting sustainable land management practices to regulate surface energy fluxes, enhance climate resilience, and reduce heat stress in cities undergoing rapid urbanization.

4 Conclusion

The surface energy balance, land cover change, and thermal patterns of the decadal (2014-2024) spatiotemporal analysis show significant anthropogenic influence on the study site due to the rapid pace of urbanization in Ahmedabad, India. The urban microclimate has been significantly changed by a 9% increase (from 27% to 36%) in a built-up area and a 4.6% decrease in vegetative cover (i.e., NDVI: 0.411 to 0.392). In correspondence, there was an increase of 3.16°C realized in Land Surface Temperature (LST) (i.e., 38.14°C to 41.3°C), which translated to a significant urban heat island effect. An improvement in net radiation (Rn) of 7.7% (416.66W/m² to 448.9W/m²) occurred as a result of decreasing albedo and an increase in impervious surfaces. The most significant energetic factor that dominated was sensible heat flux (H), which still amounted to more than 340 W/m², especially in the years with a decreased vegetation cover and an increase in surface temperatures, like 2023. Conversely, latent heat flux (LE) and evapotranspiration (ET) were subject to less variability and consistently lower values (LE: 40–60 W/m²), particularly in the summer, due to the cooling effect of urban expansion being counteracted by evaporation. There was a significant positive relationship between the Rn and the LST ($R^2 = 0.763$) and between LE and ET ($R^2 = 0.780$), while H had an inversely proportional relationship with ET ($R^2 = 0.768$), which indicates the moderating effects of vegetation in surface energy partitioning. The results confirm that reduction in vegetative cover, increase in imperviousness, and altered surface flux dynamics are of primary concern in compensating for urban thermal stress. Thus, there is a need to strategically increase green infrastructure and urban climate resilient planning to replenish the surface energy budget and enhance urban resiliency in semi-arid environments. Future studies should extend this research by confirming the findings through ground-based observations at particular sites and by applying this remote sensing-based SEBAL methodology to other cities with comparable semi-arid climates and urban development challenges.
